Risk Attitudes, Sample Selection and Attrition in a

Longitudinal Field Experiment

Glenn W. Harrison, Morten I. Lau and Hong Il Yoo †

April 2019

Abstract. We evaluate the temporal stability of risk preferences using a remarkable data set that combines socio-demographic information from the Danish Civil Registry with information on risk attitudes from a longitudinal field experiment. Our econometric model accounts for endogenous sample selection and attrition processes that may confound inferences about temporal stability. Our experimental design builds in randomization on the incentives for participation that facilitates empirical identification of the model. In general, we find evidence consistent with temporal stability after correcting for the effects of selection and attrition. When neglected, these effects change our inferences in an economically and statistically significant manner.

Appendices A through F are available online.

1. Introduction

Any longitudinal survey or experimental design raises concerns about sample selection and attrition, and response rates may vary dramatically depending on the nature of the study and incentives provided in the design. Controlling for endogenous effects of sample selection requires some background information on subjects who did not select into the survey or experiment, so that one can estimate a latent selection process and its correlation with the primary outcome of interest. This information is often missing, and most longitudinal studies are concerned just with attrition effects. For non-participants, attrition outcomes are also missing, and strictly speaking one cannot control for attrition effects without addressing endogenous selection first. Without controlling for selection effects, the estimates of a latent attrition process may be subject to selection bias even when there is no effect of selection on the primary outcome in the initial wave of the study.

Using a structural model of risky choices which allows for endogenous sample selection *and* panel attrition, we analyze data from a longitudinal field experiment with a stratified sample of the adult Danish population. The data are linked to administrative data from the Civil Registry in Denmark, allowing us to observe background information on non-participants. We illustrate the importance of controlling for within-wave and between-wave effects of sample selection in the evaluation of individual risk attitudes at different points in time.

Temporal stability of risk preferences is a common assumption in evaluations of economic behavior.[1] When the potential benefits of any social insurance policy are evaluated, for example, one must know the risk preferences of the beneficiaries of the policy in order to calculate expected individual welfare (Harrison and Ng [2016]). If preferences are unstable, then what might be a socially attractive policy today could become an unattractive policy in the future. When "nudges" or "boosts" are provided to improve decision-making over risky portfolios, to take another example, one must also condition these

---

[1] The term stability can mean unconditional stability or it can mean stable preferences conditional on a given set of covariates. In the latter case the question is whether preferences are a stable (and known) *function* of those covariates (Andersen, Harrison, Lau and Rutström [2008b; §2]). We consider both forms of stability.

on knowledge of the risk preferences of the target population in order to ensure that they are welfare-enhancing (Harrison and Ross [2018]). If those preferences are unstable over time, what might seem like a welfare-enhancing nudge today could again become a welfare-reducing nudge in the future. Behavioral welfare economics requires that we not only identify risk preferences, but check their stability over time as policies that are contingent on those preferences take effect.

Testing the assumption of temporal stability of risk preferences with the same individuals requires, of course, that one address problems of sample selection and attrition. We design and evaluate a longitudinal field experiment with a nationally representative sample of Danish adults between 19 and 75 years of age to address this question. The sample is randomly drawn from the Civil Registry and stratified with respect to population size in each county. Our design builds in explicit randomization on the incentives for participation, an idea suggested by the theoretical literature on sample selection models and easy to implement in the sampling process and subsequent experiment.

The classic problem of sample selection refers to possible recruitment biases, such that individuals with certain types of characteristics are more likely to be in the observed sample. The statistical problem is that there may be some unobserved characteristics which simultaneously affects someone's chance of being in the sample as well as affecting other outcomes that the analyst is interested in. In any longitudinal study, there is also an inherent scope for post-recruitment selection bias due to panel attrition, which occurs as some subjects may leave the panel.[2] We build on the direct likelihood approach of Heckman [1976], Hausman and Wise [1979] and Diggle and Kenward [1994] and use maximum simulated likelihood to estimate unique probit-kernel models that consider the full longitudinal design of the experiment. Our models control for the effects of selection and attrition on risk preferences inferred from both waves of

[2] The attrition problem is not the same as the dropout problem. As stressed by Heckman, Smith and Taber [1998], the latter refers to subjects that leave some randomized program or intervention, but that remain in the sample. The attrition problem concerns subjects that completely drop out of the sample.

the experiment, as well as addressing unobserved heterogeneity in risk preferences of the underlying population.

We consider a structural analysis of two theories of decision making under risk, Expected Utility Theory (EUT) and Rank Dependent Utility (RDU), where the latter is a highly influential alternative to EUT that relaxes the independence axiom under EUT.[3] Each theory has a set of structural parameters that characterize risk preferences. Previous analyses of temporal stability do not control for recruitment bias, and focus either on population averages of the structural parameters or on individual-level estimates which have no structural link to the population distribution of risk preferences. In contrast, our analysis controls for endogenous sample selection and attrition, and captures unobserved heterogeneity around the population averages by modeling all structural parameters as individual-level random coefficients that follow a population distribution. We allow the population distribution to vary over time, and the random coefficients to be correlated with the error terms in the selection and attrition equations.

This estimation approach allows us to consider temporal stability of risk attitudes at two different levels, with and without controls for endogenous sample selection and attrition: (i) the population level, by comparing the population distributions of structural parameters over time, and (ii) the individual level, by considering the correlation between individual-specific random coefficients over time. Our direct likelihood approach is inspired by the trivariate probit model of Capellari and Jenkins [2004], which includes two different types of selection equations, but their primary outcome equation is the linear index probit model and their selection equations do not address selection bias in the sense of recruitment bias.

---

[3] There is considerable experimental evidence that points to violations of the independence axiom under EUT, at least for some individuals. Several earlier alternatives to EUT relaxed the independence axiom in ways that maintained the linearity of indifference curves in the Marschak-Machina triangle representation, but experimental evidence quickly rejected those alternatives in favour of models that had non-linear indifference curves. RDU has emerged as the most popular alternative in the literature that allows for these types of violations of the independence axiom in the gain domain. Starmer [2000] provides an excellent review of these developments.

We are not aware of past statistical models that capture unobserved heterogeneity in latent structural parameters with controls for recruitment bias and/or attrition bias in longitudinal studies, or empirical studies that use the "panel correlations" of preference parameters to measure individual temporal stability.

No existing studies test temporal stability of risk attitudes in the context of a model that addresses *unobserved preference heterogeneity* across the population. Glöckner and Pachur [2012] and Zeisberger, Vrecko and Langer [2012] are so far the only studies that test temporal stability of risk preferences at the individual level. But they do not consider temporal stability at the population level and do not control for sample selection or attrition bias.

Existing studies on temporal stability of risk attitudes do not control for *selection bias or attrition bias*.[4] In fact, most studies do not even make a passing reference to "sample selection" and, perhaps more remarkably, "attrition" or "retention."[5] Dasgupta, Gangadharan, Maitra and Mani [2017] reports a significant difference in the sample average risk attitudes of the attrited and the retained, but does not undertake statistical correction for attrition bias based on *unobservables*, and does not mention selection bias.

We draw several conclusions from our statistical analysis. First, we find evidence that *the use of different fixed recruitment fees can affect the decision to participate in our experiment*.[6] When we used a relatively substantial recruitment fee of 500 kroner, which is about 100 US dollars, 24.1% of invitees accepted the

---

[4] Andersen, Harrison, Lau and Rutström [2008b] is a hybrid, viewing the sample in their first wave as the population that is then selected into later waves, and model the sample selection into later waves.

[5] Smidts [1997], Goldstein, Johnson and Sharpe [2008], Baucellis and Villasís [2010], Glöckner and Pachur [2012] and Zeisberger, Vrecko and Langer [2012].

[6] Paying no fixed recruitment fee is not a panacea for the sample selection issues we consider: it just masks it, and makes it impossible to evaluate since there is no variation in those fees. There are other sensible reasons why one should avoid zero show-up fees, since that could generate altogether different, and nasty, biases in sample selection documented by Kagel, Battalio and Walker [1979] and Eckel and Grossman [2000].

invitation to the initial wave of our experiment. The initial acceptance rate fell to 18.1% when we instead used 300 kroner. Of course, this is just a "law of demand" effect from paying more money for people to participate, but demonstrates that there are indeed deliberate decisions being made about participation. The second wave of our experiment paid the same recruitment fee of 300 kroner to every person, and there was no significant difference in the retention rates of subjects who were initially recruited with the high fee (48.4%) and subjects who were initially recruited with the low fee (54.7%).

Second, we find evidence that *correcting for endogenous sample selection and panel attrition changes our inferences about risk preferences in an economically and statistically significant manner*. The results suggest that one should not discount the potential effects of selection and attrition *a priori*, even when a self-selected sample and an underlying population of interest look more or less similar in terms of *observed* characteristics. Subjects participating in each wave of our experiments have demographic characteristics that are comparable to the adult population in Denmark, but without correcting for endogenous selection and attrition our EUT specification would have overestimated the average Dane's relative risk aversion in the first wave by a factor of about 2. Under RDU, non-linear probability weighting, capturing pessimism or optimism in relation to objective probabilities, may generate a positive or negative risk premium even when the individual has a linear utility function. Without correction for endogenous selection and attrition, our RDU specification would have substantially underestimated the population share of individuals who have an "inverse-S" probability weighting function that captures optimism for small probabilities and pessimism for large probabilities.

Finally, we draw *several conclusions on temporal stability of risk preferences that depend on which aspect of temporal stability one is interested in*. The range of results reflect the strengths of our empirical specifications that allow us to define and test temporal stability in several ways. For example, consider risk aversion in the EUT sense of a concave utility function. Under both EUT and RDU, we find that the average Dane is risk averse in this sense, and this conclusion is robust over time. But we still find some instability in the population distribution of risk aversion under RDU as there is a decline in the extent of unobserved preference heterogeneity around the average. When focusing on the within-individual autocorrelation of risk aversion, we find estimates of 0.36 under EUT and 0.69 under RDU, which lie between the two extreme cases of completely unrelated and completely stable preferences. Of course, under RDU risk preferences are also characterized by the probability weighting function. We find more evidence on the stability of the probability weighting function than for the utility function, both at the population and individual levels. Overall, we find evidence consistent with temporal stability under EUT and RDU at the aggregate population level.

Our use of exogenously varied recruitment fees demonstrates how one can constructively design features of a survey or experiment to facilitate empirical identification of sample selection effects. Building on Heckman [1976][1979], the emphasis in the literature has been on the discovery of some "exclusion restrictions," referring to variables that affect the probability of selection but do not affect the primary outcome of interest.[7] The collection of these variables could be designed by the surveyor or experimenter, but often were not.[8] In most cases analysts simply have to live with the existing set of variables in a survey or experiment, and search for exclusion restrictions on an *a priori* basis. The later theoretical literature, typified by Das, Newey and Vella [2003], stresses the value of direct controls over the probability of selection, rather than relying on some variables selected on an *a priori* basis.

---

[7] Without such "exclusion restrictions," identification of sample selection models has to rely on the validity of functional form assumptions alone, such as the bivariate normality of the error terms in the maximum likelihood estimation of the standard Heckman model. Identification in this instance is formally achieved, but is known to be "weak" (Meng and Schmidt [1985] and Keane [1992]). Exclusion restrictions are formally required for identification when semi-parametric specifications are used (Lee [1995]).

[8] We know of only two applications of the constructive approach to building exclusion restrictions into the experimental design. Appendix B provides a review of the related studies. It is folklore in survey research that information is often retained on how many calls were made to a subject, how hard they were to contact in other ways, or which interviewer conducted the survey. Although not the object of randomization, information of this kind might be used as an instrument to model the probability of selection.

2. Data

A. Field Sampling Procedures

Between September 28 and October 22, 2009 we conducted an artefactual field experiment[9] with 413 Danes.[10] The sample was drawn to be representative of the adult population as of January 1, 2009, using sampling procedures that are virtually identical to those documented in Andersen, Harrison, Lau and Rutström [2008a]. We received a random sample of the population aged between 18 and 75, inclusive, from the Danish Civil Registration Office, stratified the sample by geographic area, and sent out 1,996 invitations. We drew this sample of 1,996 invitees from a random sample of 50,000 adult Danes obtained from the Danish Civil Registration Office, which includes information on sex, age, residential location, marital status, and whether the individual is an immigrant. Thus we are in the fortunate, and rare, position of knowing some basic demographic characteristics of the individuals that do *not* agree to participate in our experiment.[11]

At a broad level our final sample is representative of the population: the sample of 50,000 subjects had an average age of 49.8, 50.1% of them were married, and 50.7% were female; our final sample of 413 subjects had an average age of 48.7, 56.5% of them were married, and 48.2% were female. We stress this

---

[9] An artefactual field experiment is defined by Harrison and List [2004] as involving the use of artefactual instructions, task and environment with a field subject pool.

[10] The negative effects of the global financial crisis of 2007 and 2008 were largely in place by the time of our experiments, between September 2009 and October 2010. On the other hand, the European sovereign debt crisis was just starting to manifest when our experiments began, and Denmark was about to begin a fiscal budgetary crisis in 2010 that persisted for several years. A detailed account of Denmark's responses to these crises is provided by Kickert [2013].

[11] It is possible to extend this list of characteristics by taking our experimental data to Statistics Denmark, which stores the same data that we obtained from the Civil Registration Office, and merging it with the entire set of data that is available on all of the invited subjects. One can then undertake the same statistical analyses but with a larger set of covariates to explain sample selection.

comparison because it is often made to assuage concerns about sample selection: check if the final sample is similar to the population for a few observed characteristics, and then assume it is representative in all characteristics, including those that are latent and unobserved. In the absence of the type of data we have access to in Denmark, this may appear to be a reasonable "second best" procedure, but our results show that it may be an inadequate check on endogenous sample selection effects.

The initial recruitment letter for the experiment explained the purpose and that it was being conducted by Copenhagen Business School. The letter clearly identified that there would be fixed and stochastic earnings from participating in the survey. In translation, the uncertainty was explained as follows:

> **You can win a significant amount**
> To cover travel costs, you will receive 500 kroner at the end of the meeting. Moreover, each participant will have a 10 percent chance of receiving an amount between 50 and 4,500 kroner in one part of the survey. In another part of the survey, each participant will have a 10 percent chance of receiving at least 1,500 kroner. Some of these amounts will also be paid out at the end of the meeting, and some amounts will be paid out in the future. A random choice will decide who wins the money in the different parts of the survey.

The fixed amount is 500 kroner in the treatment that this text comes from, and 300 kroner in another treatment. Subjects were randomly assigned to one of these two recruitment treatments. The stochastic earnings referred to in the recruitment letter were for a risk aversion task and separate tasks eliciting time preferences.[12] Thus the subjects should have anticipated the use of randomization in the experiment.

The experiments were conducted in hotel meeting rooms around Denmark, so that travel logistics for the invited sample would be minimized. The average home-to-hotel distance was slightly larger for the 1583 non-participants than the 413 participants (10.2 miles vs 8.1 miles), suggesting that distance might have had some influence on their participation decisions.[13] Various times of day were also offered to

[12] Results from the discounting task are reported in Andersen, Harrison, Lau and Rutström [2013][2014], and results from the correlation aversion task are reported in Andersen, Harrison, Lau and Rutström [2018].

[13] The 2.1-mile difference, albeit small, is statistically significant with a two-sided p-value < 0.001.

subjects, to facilitate a broad mix of attendance. The largest session had 15 subjects, but most had fewer. The procedures were standard: Appendix A documents an English translation of the instructions, and shows a typical screen display for the risk aversion task. Subjects were given written instructions which were read out and then made choices in a trainer task for small non-monetary rewards. The trainer task was "played out" and illustrated the procedures in the experiment. All decisions were made on computers. After all choices had been made the subject was asked a series of standard socio-demographic questions.

There were 40 risk attitude choices and 40 discounting choices, and each subject had a 10% chance of being paid for one choice in each block of 40 choices.[14] The risk attitude choices preceded the discounting choices in one treatment, and *vice versa* in another treatment. Average payments for the risk attitude choices were 242 kroner, and average payments for the discounting choices were 201 kroner (although some were for deferred receipt), for a combined average of 443 kroner. The exchange rate at the time was close to 5 kroner per U.S. dollar, so expected earnings from these tasks combined were $91. The subjects were also paid a 300 kroner or 500 kroner fixed show-up fee, plus earnings from subsequent tasks.[15]

To derive distances, we downloaded geographical coordinates of relevant locations from *Google Maps* and applied software due to Picard [2010] that measures the length of the shortest curve between two locations over an estimated surface of the earth.

[14] The number of subjects in each session varied between 3 and 15, which is independent of the 10% probability of being paid for one of the 40 risk attitude choices. Harrison, Lau and Williams [2002] randomly selected one subject in each session of their Danish field experiment to actually pay out their discounting choices, and find a small positive, but statistically insignificant, effect of group size on elicited discount rates.

[15] An extra show-up fee of 200 kroner was paid to 24 subjects who had received invitations stating 300 kroner, but then received a final reminder that accidentally stated 500 kroner. The additional tasks earned subjects an average of 659 kroner, so total earnings from choices made in the session averaged 1102 kroner, or roughly $221, in addition to the fixed fee of $60 or $100. These 24 subjects were treated

Between April 2010 and October 2010 we repeated the risk aversion and discounting tasks with 182 of the 413 subjects who participated in the first experiment.[16] Each subject was interviewed in private in the new experiment, and the meeting was conducted at a convenient location for them (e.g., their private residence or the hotel where the first experiment took place). All subjects were paid a fixed fee of 300 kroner for their participation in the second experiment.[17]

Table 1 provides the sample response in each panel wave, and definitions of the explanatory variables used in the statistical analysis and summary statistics. We observe a significant difference in sample response with the high recruitment fee compared to the low recruitment fee. The drop from 24.1% to 18.1% in the first wave is statistically significant according to a Fisher Exact test, with a *p*-value less than 0.001. After participating in the first wave, the sample response to recruitment into the second wave was slightly lower for those recruited into the first wave with the high recruitment fee compared to

---

in the analysis as if they were 300 kroner subjects, since that was the incentive in the original invitation. Treating them as 500 kroner subjects does not change the results.

[16] There were four steps in the construction of this sub-sample. First, we divided the country into five regions, and each region was divided into sub-regions. Each sub-region was assigned 1 or 2 numbers, in rough proportionality to the population of the sub-region. In total we assigned 24 numbers. Second, although Denmark is a relatively small country, it was necessary to consider logistical constraints, and we randomly picked 12 of the 24 numbers for the experiment in April 2010 and the remaining 12 numbers for the experiment in October 2010. Third, we picked the first 50% of the randomly sorted records within each sub-region. This provided a sub-sample of 100 subjects for each experiment. Fourth, we contacted subjects by phone and invited them to participate again in the experiments.

[17] We did not vary the recruitment fee in the second experiment because we offered to interview the subjects at home or the hotel where the first experiment was conducted. The experiments were time consuming and expensive to conduct, and we paid subjects the low recruitment fee of 300 kroner in the second experiments to keep costs down. We certainly see value from varying recruitment fees in the second stage as well.

those recruited with the low fee. The sample response rates were 48.4% and 54.7% in the second wave, and are not statistically different according to a Fisher Exact test with a two-sided *p*-value of 0.24. One might infer from these statistics that the effects of attrition on elicited risk attitudes are not significant, but of course that depends on who responded, which can only be assessed with an appropriate statistical model.

B. Experiments to Infer Risk Attitudes

Risk attitudes were evaluated from data in which subjects made a series of binary lottery choices. For example, lottery A might give the individual a 50-50 chance of receiving 1600 kroner or 2000 kroner to be paid today, and lottery B might have a 50-50 chance of receiving 3850 kroner or 100 kroner today. The subject picks A or B. We used the procedures of Hey and Orme [1994], and presented each binary choice to the subject as a "pie chart" showing prizes and probabilities.[18] We gave each subject the same set of 40 choices, in four sets of 10 choices with the same prizes. The prize sets employed are: [A1: 2000 and 1600; B1: 3850 and 100], [A2: 1125 and 750; B2: 2000 and 250], [A3: 1000 and 875; B3: 2000 and 75] and [A4: 2250 and 1000; B4: 4500 and 50]. The order of these four prize sets was randomized for each subject, with the probabilities varying within each set of 10 choices.[19] We refer to the first and last of these four prize sets as the "high stakes" lotteries compared to the "low stakes lotteries" in the second and third set. These four treatments with different prize sets were administered within subjects.

[18] The use of "pie charts" is common in experimental elicitation of risk preferences, but should not be viewed as the only way that one might present lottery choices. Arguably, probabilities appear more salient than prizes in a pie chart, since probabilities are displayed both graphically (as pie slices) and numerically, whereas prizes are only displayed numerically. Harrison and Rutström [2008; Appendix A] review alternative ways of presenting lotteries in the literature, none of which has emerged as obviously superior for all purposes.

[19] Within each prize set the 10 choices were presented one at a time in an ordered manner, with the probability of the high prize starting at 0.1 and increasing by 0.1 until the last choice is between two certain amounts of money.

We asked each subject to respond to all 40 risk aversion tasks and then randomly decided which one to play out using numbered dice. The large incentives and budget constraints precluded us from paying all subjects, so each subject was given a 10% chance to actually receive the payment associated with his decision. The typical findings from lottery choice experiments of this kind are that individuals are generally averse to risk, and that there is considerable heterogeneity in risk attitudes across subjects: see Harrison and Rutström [2008] for an extensive review.

3. Identification of Risk Preferences

We first write out a structural model to estimate risk attitudes assuming EUT, to focus on essentials. We then discuss how the likelihood function changes to account for sample selection and attrition, and then finally discuss the extension from EUT to the more general RDU model.

A. Baseline EUT Specification

Consider the estimation of risk preferences in the simplest possible model of decision-making under risk, EUT, without worrying about sample selection or attrition. In our experiment, each decision task presented a choice between two lotteries, and each lottery had two potential outcomes. Let M_{ij} be the j^{th} outcome of lottery i, where i=A,B and j=1,2. Assume that the utility of an outcome is given by the constant relative risk aversion (CRRA) specification

$$U(M_{ij}) = M_{ij}^{(1-r)}/(1-r) \tag{1}$$

for $r \neq 1$, where r is the CRRA coefficient. Then, under EUT, $r=0$ denotes risk neutral behavior, $r>0$ denotes risk aversion, and $r<0$ denotes risk loving behavior.

EUT predicts that the observed choice is lottery B when it gives the larger expected utility (EU) than lottery A and *vice versa*. Probabilities for each outcome, $p(M_{ij})$, are those that are induced by the experimenter, so the EU of lottery i is simply the probability weighted average of its outcome utilities,

$$EU_i = p(M_{i1}) \times U(M_{i1}) + p(M_{i2}) \times U(M_{i2}), \tag{2}$$

where $p(M_{i2}) = 1 - p(M_{i1})$. Let y denote a binary indicator of whether the observed choice is lottery B (y = 1) or lottery A (y = 0). Using the indicator function $\mathbf{I}[.]$, the observed choice under EUT can be compactly written as $y = \mathbf{I}[(EU_B - EU_A) > 0]$.

To allow observed choices to deviate from deterministic theoretical predictions, the EUT model is combined with a stochastic behavioral error term. Specifically, assume that the choice depends not only on the EU difference, but also on a random error term $\boldsymbol{\varepsilon}$ such that $y = \mathbf{I}[(EU_B - EU_A) + \upsilon \times \boldsymbol{\varepsilon} > 0]$, or equivalently $y = \mathbf{I}[(EU_B - EU_A)/\upsilon + \boldsymbol{\varepsilon} > 0]$, where υ is a positive scale factor that we will parameterize shortly. Assume further that $\boldsymbol{\varepsilon}$ is normally distributed with the standard deviation of μ, $\boldsymbol{\varepsilon} \sim N(0, \mu^2)$. The choice probability of lottery B is then $\Phi(\nabla EU)$ where $\Phi(.)$ is the standard normal cumulative density function (CDF), and the index ∇EU is given by

$$\nabla EU = [EU_B - EU_A)/\upsilon]/\mu. \tag{3}$$

It follows that the likelihood function for each choice observation takes the form

$$P(r, \mu) = \Phi(\nabla EU)^y \times (1 - \Phi(\nabla EU))^{(1-y)}. \tag{4}$$

As the noise parameter μ approaches 0, this stochastic EUT specification collapses to the deterministic EUT model; conversely, as μ gets arbitrarily large, it converges to an uninformative model which predicts a 50:50 chance regardless of the underlying EU difference.

We complete the behavioral error specification by adopting the contextual utility model of Wilcox [2011]: υ is set to $(U_{max} - U_{min})$, where U_{max} and U_{min} are the maximum and minimum of the four potential outcome utilities, $U(M_{A1})$, $U(M_{A2})$, $U(M_{B1})$ and $U(M_{B2})$. Supposing that lottery B is riskier than lottery A, it is arguably desirable to have a statistical model that predicts a smaller probability of choosing B for a more risk averse person with a larger r. The traditional Fechner error model ($\upsilon = 1$) leads to choice probabilities that do not vary monotonically with r in this manner, an issue identified by Wilcox [2011] and reiterated by Apesteguia and Ballester [2018].[20] The contextual utility model addresses this potential drawback.

To clarify our econometric methods, more notation is needed than one would typically see in the context of non-linear models for panel data. We subscript the choice-level likelihood function in (4) as $P_{ntw}(r_{nw}, \mu)$ henceforth, to emphasize that it describes subject n's choice in decision task t of panel wave w.[21] The CRRA coefficient r_{nw} is indexed by subject n and wave w for two reasons. First, to capture

[20] In Appendix F, we re-estimate our main models assuming the Fechner error specification.

[21] We repeated the same set of experiments across two panel waves, and within each wave the

unobserved preference heterogeneity across individuals, we model the CRRA coefficient as an individual-specific random coefficient drawn from a population distribution of risk preferences. Second, to test temporal stability, we allow the underlying population distribution, as well as the CRRA coefficient drawn from it, to vary freely across waves. We use $f(r_{n1}, r_{n2}; \theta)$ to denote the joint density function for the random CRRA coefficients, where θ is a set of parameters that characterize their joint distribution.

It is possible to estimate the set of parameters θ directly and draw inferences about the population distribution of risk preferences, once the joint density $f(r_{n1}, r_{n2}; \theta)$ is fully specified. Assume that r_{n1} and r_{n2} are jointly normal so that $\theta = (\bar{r}_1, \bar{r}_2, \sigma_{r1}, \sigma_{r2}, \sigma_{r1r2})$, where $\bar{r}_w$ and σ_{rw} are the population mean and standard deviation of the CRRA coefficient r_{nw}, and σ_{r1r2} is the covariance between r_{n1} and r_{n2}. Conditional on a particular pair of CRRA coefficient draws, the likelihood of observing a series of 40 or 80 choices made by subject n can be specified as

$$\begin{aligned} CL_n(r_{n1}, r_{n2}, \mu) &= \prod_t P_{nt1}(r_{n1}, \mu) && \text{if } s_{n2} = 0 \\ &= \prod_t P_{nt1}(r_{n1}, \mu) \times \prod_t P_{nt2}(r_{n2}, \mu) && \text{if } s_{n2} = 1 \end{aligned} \tag{5}$$

where s_{n2} is an indicator of whether subject n participated in only the first panel wave ($s_{n2} = 0$) or both panel waves ($s_{n2} = 1$). Since r_{n1} and r_{n2} are modeled as random coefficients, the "unconditional" (Train [2009, p.146]) or actual likelihood of subject n's choices is then obtained by taking the expected value of $CL_n(r_{n1}, r_{n2}, \mu)$ over the joint density $f(r_{n1}, r_{n2}; \theta)$

$$L_n(\bar{r}_1, \bar{r}_2, \sigma_{r1}, \sigma_{r2}, \sigma_{r1r2}, \mu) = L_n(\theta, \mu) = \iint CL_n(r_{n1}, r_{n2}, \mu) f(r_{n1}, r_{n2}; \theta) dr_{n1} dr_{n2}. \tag{6}$$

Unobserved heterogeneity is similarly integrated out from many textbook models for panel data, such as random effects probit (Wooldridge [2010, p.613]).[22] Our application is distinctive because unobserved

---

subject completed a series of decision tasks over 40 lottery pairs. The outcomes and probabilities associated with lottery pairs vary from task to task, and the same subject may make different choices across tasks and waves. Each lottery outcome and its probability are then M_{ijntw} and $p(M_{ijntw})$, leading to the expected utilities EU_{intw} and the index function ∇EU_{ntw}. The indicator y_{ntw} is 1 (0) if subject n chooses lottery B (lottery A) in decision task t of the experiment in wave w.

[22] Much as one finds with a random effect probit model, our random coefficient model allows for panel correlation across repeated observations on the same individual. Although (5) is a product formula

heterogeneity enters the index function ∇EU_{ntw} non-linearly via the CRRA coefficient, and varies across two wave-specific blocks of observations instead of being time-invariant.[23] The unconditional likelihood function $L_n(\theta, \mu)$ does not have a closed-form expression, but can be approximated using simulation methods (Train [2009, p.144-145]). We compute maximum simulated likelihood (MSL) estimates of risk preference parameters θ and the behavioral noise parameter μ by maximizing a simulated analogue to the sample log-likelihood function $\sum_n \ln(L_n(\theta, \mu))$. The estimation sample is 413 subjects who participated in the first experiment *or* both experiments.

Our modeling framework offers several ways to define and analyze temporal stability of risk attitudes. One can test if the entire population distribution of risk preferences is stable, which can be expressed as a joint hypothesis H_0: $\bar{r}_1 = \bar{r}_2$ and $\sigma_{r1} = \sigma_{r2}$. Alternatively, one can test the temporal stability of the average person's risk attitude (H_0: $\bar{r}_1 = \bar{r}_2$), or test the temporal stability of unobserved preference heterogeneity (H_0: $\sigma_{r1} = \sigma_{r2}$). We can also accommodate observed heterogeneity by writing $\bar{r}_1$ and $\bar{r}_2$ as linear functions of the subject's characteristics, such as age, gender and income.[24] It is then possible to consider the question of which demographic groups tend to be more risk averse, and examine if the answer to that question is temporally stable.

The questions so far pertain to temporal stability at the population level, but the analysis can focus on temporal stability at the individual level as well. By normalizing the scale of covariance σ_{r1r2}, one can derive a coefficient $\varrho_{r1r2} = \sigma_{r1r2} / (\sigma_{r1} \times \sigma_{r2})$ that directly measures the within-individual correlation of the CRRA coefficient over time. Andersen, Harrison, Lau and Rutström [2008b] elicit risk preferences using

akin to the pooled probit model, it is only one building block for the actual likelihood function in (6) that integrates such formulas. The log of this likelihood function does not simplify into a sum of observation-level log-likelihood functions, so our statistical approach does not rely on the independence of choice observations within individuals.

[23] Methods for estimating non-linear random coefficients models of risk aversion were developed by Andersen, Harrison, Hole, Lau and Rutström [2012].

[24] For illustration, we analyze a model of male-female differences in risk attitudes in Appendix E.

multiple price list formats, and compute this type of correlation based on the midpoints of CRRA intervals that predict observed behavior under EUT. The approach we take here is far more general because it allows for behavioral errors and can be applied with any elicitation format, as long as the statistical model incorporates a random coefficient specification similar to ours. Moreover, as reported below, one can estimate the within-individual correlations of structural parameters in an analogous manner after correcting for selection and attrition biases, as well as in the context of RDU models.

B. EUT Specification with Endogenous Sample Selection and Panel Attrition

The experimental design allows us to correct for sample selection into both panel waves of the experiment.[25] Estimates of risk aversion could be sensitive to the sample selection and attrition process in any longitudinal setting, and the estimated coefficients in the behavioral model may be significantly biased if subjects condition their participation on unobservable characteristics that correlate with their latent risk preferences. It is not obvious *a priori* that individuals with stable preferences are more likely to self-select into the early or later stages of our experiment. Since the decision to participate in the experiment may be correlated with individual risk preferences, it is appropriate to account for possible sample selection and attrition effects in the statistical model.

To control for sample selection bias, we take the initial pool of 1,996 invited subjects as a random sample from the population, and model the initial selection process that lead to 413 subjects in the first experiment. From this sample, 354 subjects were invited to the second experiment. To control for panel attrition bias, we take those 354 subjects as a random sample from the sub-population that self-selected into the first experiment, and model the attrition process that led to 182 subjects in the second experiment. This general strategy is consistent with our experimental design, under which the experimenter exogenously determines whether someone is invited to the first experiment, and which subjects in the first experiment get invited to the second experiment.

---

[25] Vella [1998] surveys alternative specifications for modelling sample selection, including semi-parametric methods.

We first describe a system of binary response models that describes sample selection and attrition. Let s_{nw} be an indicator of whether subject n accepted the invitation to the experiment in wave w ($s_{nw} = 1$) or not ($s_{nw} = 0$). For those who were not invited to the second experiment, we set $s_{n2} = -1$. Assume that each observed outcome s_{nw} is determined by a latent propensity S_{nw}, such that $s_{n1} = \mathbf{I}[S_{n1} > 0]$, and $s_{n2} = \mathbf{I}[S_{n1} > 0 \cap S_{n2} > 0]$ if subject n was invited to the second experiment. The latent propensities are specified as

$$S_{n1} = X_{n1}\beta_1 + u_{n1} = X_{n1}\beta_1 + (a_{n1} + e_{n1}) \tag{7}$$
$$S_{n2} = X_{n2}\beta_2 + u_{n2} = X_{n2}\beta_2 + (a_{n2} + e_{n2}) \tag{8}$$

where X_{nw} is a vector of explanatory variables including a constant, β_w is a conformable vector of coefficients to estimate, and u_{nw} is a random disturbance. We decompose u_{nw} further into a_{nw} and e_{nw}, which are orthogonal to each other. The term a_{nw} captures unobserved characteristics which are potentially correlated with risk attitudes, and across selection and attrition processes. In contrast, e_{nw} captures purely idiosyncratic errors.

Assume that the correlated components a_{n1} and a_{n2} are bivariate normal, and that each idiosyncratic error e_{nw} is independently normal. Under this assumption, the composite errors u_{n1} and u_{n2} are also bivariate normal. When viewed in isolation from the random coefficient EUT model, the system of equations (7) and (8) is analogous to the probit model with sample selection (Van de Ven and Van Praag [1981]) which views the sample retention indicator s_{n2} as the primary outcome of interest. It is common to normalize this type of model by setting $\mathrm{Var}(u_{n1}) = \mathrm{Var}(u_{n2}) = 1$, and identify β_1, β_2 and $\varrho_{s1s2} = \mathrm{Corr}(u_{n1}, u_{n2}) = \mathrm{Cov}(a_{n1}, a_{n2})$. We could follow the same convention, but prefer to normalize the system by setting $\mathrm{Var}(u_{n1}) = 2$ and $\mathrm{Var}(u_{n2}) = 2 + \mathrm{Cov}(a_{n1}, a_{n2})$, and identify β_1, β_2 and $\sigma_{s1s2} = \mathrm{Cov}(u_{n1}, u_{n2}) = \mathrm{Cov}(a_{n1}, a_{n2})$. This scheme allows us to assume $\mathrm{Var}(a_{n1}) = \mathrm{Var}(e_{n1}) = \mathrm{Var}(e_{n2}) = 1$ and $\mathrm{Var}(a_{n2}) = 1 + \sigma_{s1s2}$ without loss of generality; then, (7) and (8) can more easily be combined with the random coefficient EUT model by attaching probit probabilities to (5), as shown below.

Let $g(a_{n1}, a_{n2}, r_{n1}, r_{n2}; \Theta)$ denote a density function for the joint distribution of risk attitudes and relevant selection/attrition errors, which is characterized by parameters in Θ. Let σ_{s1rw} and σ_{s2rw} denote $\mathrm{Cov}(a_{n1}, r_{nw})$ and $\mathrm{Cov}(a_{n2}, r_{nw})$ respectively. We allow for the full set of correlations amongst the four random components. Given the earlier assumptions, g(.; Θ) is then multivariate normal and $\Theta = (\theta, \Sigma)$, where $\theta = (\bar{r}_1, \bar{r}_2, \sigma_{r1}, \sigma_{r1,} \sigma_{r1r2})$ characterizes the population distribution of the CRRA coefficients and $\Sigma = (\sigma_{s1s2}, \sigma_{s1r1,} \sigma_{s1r2}, \sigma_{s2r1}, \sigma_{s2r2})$ collects covariance parameters that may induce selection and attrition biases. For example, a positive σ_{s1r1} means that those with relatively large CRRA coefficients in wave 1 are more likely to participate in the first experiment, and a positive σ_{s2r1} means that such subjects with high CRRA coefficients in wave 1 are also more likely to participate in the second experiment. Without correction for selection and attrition, one would overestimate the initial degree of risk aversion in the population. While σ_{s1s2} does not address risk attitudes directly, this parameter corrects the attrition process for initial selection bias, since the attrition outcomes are only observed for the self-selected sample of participants in the first experiment. If σ_{s1s2} is falsely constrained to 0, the resulting correction for attrition bias becomes invalid.

We now turn to a likelihood function which augments the baseline EUT specification with controls for selection and attrition biases. Conditional on a particular set of a_{n1}, a_{n2}, r_{n1} and r_{n2}, the joint likelihood of subject n's selection/attrition outcomes and risky choices can be specified as

$$\begin{aligned} CL_n(a_{n1}, a_{n2}, r_{n1}, r_{n2}, \beta_1, \beta_2, \mu) &= 1 - \Phi(\tau_{n1}) && \text{if } s_{n1} = 0 \\ &= \Phi(\tau_{n1}) \times \textstyle\prod_t P_{nt1}(r_{n1}, \mu) && \text{if } s_{n1} = 1, s_{n2} = -1 \\ &= \Phi(\tau_{n1}) \times (1 - \Phi(\tau_{n2})) \times \textstyle\prod_t P_{nt1}(r_{n1}, \mu) && \text{if } s_{n1} = 1, s_{n2} = 0 \\ &= \Phi(\tau_{n1}) \times \Phi(\tau_{n2}) \times \textstyle\prod_t P_{nt1}(r_{n1}, \mu) \times \textstyle\prod_t P_{nt2}(r_{n2}, \mu) && \text{if } s_{n1} = 1, s_{n2} = 1 \end{aligned} \tag{9}$$

where $\tau_{nw} = X_{nw}\beta_w + a_{nw}$, $\Phi(.)$ is the standard normal CDF and $P_{ntw}(.)$ is the choice-level likelihood under the baseline EUT model. The exact form of the conditional likelihood function thus varies for those who rejected the first invitation ($s_{n1} = 0$), those who participated in the first experiment but did not receive the second invitation ($s_{n1} = 1$, $s_{n2} = -1$), those who participated in the first experiment but rejected the second invitation ($s_{n1} = 1$, $s_{n2} = 0$), and finally those who participated in both experiments ($s_{n1} = s_{n2} = 1$). The unconditional likelihood function for subject n can be obtained by taking the expected value of $CL_n(a_{n1}, a_{n2}, r_{n1}, r_{n2}, \beta_1, \beta_2, \mu)$ over the joint distribution of the four random components

$$L_n(\Theta, \beta_1, \beta_2, \mu) = \iiiint CL_n(a_{n1}, a_{n2}, r_{n1}, r_{n2}, \beta_1, \beta_2, \mu) g(a_{n1}, a_{n2}, r_{n1}, r_{n2}; \Theta) da_{n1} da_{n2} dr_{n1} dr_{n2.} \tag{10}$$

where $\Theta = (\bar{r}_{1,} \bar{r}_2, \sigma_{r1}, \sigma_{r2,} \sigma_{r1r2}, \sigma_{s1s2}, \sigma_{s1r1,} \sigma_{s1r2}, \sigma_{s2r1}, \sigma_{s2r2})$ in full. Since (10) does not have a closed form expression, we compute the MSL estimates of Θ, β_1, β_2, and μ by maximizing a simulated analogue to the sample log-likelihood function $\sum_n \ln(L_n(\Theta, \beta_1, \beta_2, \mu))$. The estimation sample is all 1,996 subjects who were invited to the first experiment.

Parametric models with selection and attrition such as ours are theoretically identified without the aid of cross-equation exclusion restrictions. Nevertheless, our experimental design provides natural candidates for such restrictions that we use to assist empirical identification. The initial invitation letter randomized subjects to different recruitment fees, and the longitudinal design allows us to observe each subject's additional earnings from the first experiment.[26] Before coming to the first experiment, subjects did not know anything about the 40 lottery pairs used and, during the first experiment, everyone faced the same set of 40 lottery pairs. We assume that the recruitment fees affect the initial decision to accept the first invitation, but do not affect the decision to accept the second invitation once we control for additional earnings from the first experiment.[27] We maintain the usual hypothesis that the recruitment fees and prior earnings do not affect the subject's evaluation of lottery pairs directly. Finally, subjects had to travel to hotel meeting rooms to participate in the first experiment, whereas each subject chose their own preferred venue for the second experiment.

---

[26] Since the recruitment fee is an observed characteristic and the model is theoretically identified without utilizing this as an exclusion restriction, it is possible to test whether the use of different recruitment fees results in recruitment of subjects with systematically different risk attitudes. For instance, as shown in Table C5 and Table C6 of Appendix C, we can condition the mean of each structural parameter (r_{n1} and r_{n2} under EUT, and r_{n1}, r_{n2}, φ_{n1}, and φ_{n2} under RDU that we will describe shortly) on the recruitment fee indicator and study whether the estimated coefficient on that indicator is significant. The results support our intended use of the recruitment fee as an exclusion restriction to assist empirical identification. The recruitment fee has an insignificant effect on the mean of r_{n1} and r_{n2} under EUT with *p*-values of 0.173 and 0.447, and under RDU with *p*-values of 0.191 and 0.246. Similarly the recruitment fee has an insignificant effect on the mean of φ_{n1}, and φ_{n2} under RDU, with *p*-values of 0.997 and 0.295.

[27] Additional earnings in the first experiment include payments for choices in three sets of decision tasks which elicit individual risk attitudes, discount rates and correlation aversion, respectively.

The preceding discussion motivates us to include the recruitment fees only in X_{n1} for the selection equation, the actual earnings from the first experiment only in X_{n2} for the attrition equation, and the lottery payoffs and probabilities only in ∇EU_{njt} for the structural model of risky choices. In addition, we augment X_{n1} with each subject's home-to-hotel distance (in miles) and its square.[28] Both X_{n1} and X_{n2} also include the subject's age and gender, and X_{n2} additionally includes self-reported income that is only available for those who participated in the first experiment.

To see the flexibility of our extended specification, one may compare it with several special cases. Consider first a "naïve" approach, in which each panel wave is evaluated separately, using (7) to correct for selection into the first wave and (8) to correct for selection into the second wave. This approach is naïve in the sense that it fails to recognize the longitudinal nature of the experiments, and requires $\sigma_{s1s2} = \sigma_{s1r2} = \sigma_{s2r1} = 0$. However, even when these restrictions are valid, the approach cannot identify σ_{r1r2} and hence ϱ_{r1r2} that measures the temporal stability of risk preferences within individuals. Two special cases arise if both waves are analyzed jointly, but they correct for only selection bias or attrition bias. With correction for selection bias only, one can estimate all structural parameters consistently when $\sigma_{s2r1} = \sigma_{s2r2} = 0$. The other special case ignores selection bias and requires $\sigma_{s1s2} = \sigma_{s1r1} = \sigma_{s1r2} = 0$. The latter case is perhaps more interesting, considering that it resembles what one would do in typical longitudinal studies that observe no information on those who did not participate in the first wave.

Our modeling strategy provides a general framework for the structural estimation of risk preferences with correction for endogenous selection and attrition. While we parameterize the statistical model using multivariate normal densities and probit kernels, with a few notational changes the likelihood

---

[28] How closely the home-to-hotel distance approximates the actual inconvenience involved in travelling is an open question. The validity of our statistical corrections for endogenous selection and attrition does not rely on any precise interpretation that one might place on the distance variable. As usual, the selection equation in our framework is a reduced-form index model and its coefficients need not have any causal interpretation.

functions above can incorporate other joint distributions of $\{a_{n1}, a_{n2}, r_{n1}, r_{n2}\}$ and kernel CDFs. We focus on the multivariate normal-probit kernel specification primarily to reach a wider audience; the workhorse sample selection models in the empirical literature assume either the bivariate normality of selection and structural errors in a maximum likelihood framework, or the marginal normality of selection errors in Heckman's two-step procedure. In many longitudinal studies, the researcher may apply correction for panel attrition but not for initial selection due to the lack of information on non-participants. Our econometric approach can be adapted to such settings to specify a structural model with endogenous attrition, by omitting the selection equation and re-normalizing the standard deviation of the attrition error.[29] As usual, the resulting correction for attrition bias would be a second-best solution that presumes the absence of selection bias.

C. Rank Dependent Utility Theory Specifications

RDU is a popular generalization of EUT, due to Quiggin [1982], that allows the decision-maker to transform the objective probabilities presented in lotteries and use these weighted probabilities to determine decision weights when evaluating lotteries. If w(p) is the probability weighting function assumed, and each lottery has only two prizes such that $M_{i1} > M_{i2}$, then we have

$$RDEU_i = [\ w(p(M_{i1})) \times U(M_{i1})\ ] + [\ (1\text{-}w(p(M_{i1}))) \times U(M_{i2})\ ], \tag{2′}$$

where $RDEU_i$ refers to rank dependent expected utility of lottery i, and the remaining notation is as defined in the context of (2).

The logic behind our econometric specifications extends naturally to RDU, once we replace EU_i with $RDEU_i$. Of course, one has to specify the functional form for w(p) and estimate additional

[29] The conditional likelihood function under this endogenous attrition model is algebraically equivalent to the special case of (9) that assumes $s_{n1} = 1$ and $\Phi(\tau_{n1}) = 1$ for every n. Since the covariance between the selection and attrition errors is no longer identified, the scale of the attrition error should be re-normalized, for example by setting $Var(u_{n2}) = 2$.

parameters. Prelec [1998] offers a two-parameter probability weighting function that exhibits considerable flexibility. This function is

$$w(p) = \exp\{-\eta(-\ln p)^{\varphi}\}, \tag{12}$$

and is defined for $0<p<1$, $\eta>0$ and $\varphi>0$. We use its one-parameter special case that assumes $\eta = 1$, and model φ as a log-normally distributed random coefficient φ_{nw} that varies across individuals and panel waves. The resulting one-parameter function exhibits inverse-S probability weighting (optimism for small p, and pessimism for large p) for $\varphi < 1$, S-shaped probability weighting (pessimism for small p, and optimism for large p) for $\varphi > 1$, and linear probability weighting that reduces RDU to EUT when $\varphi = 1$. It rules out the cases of globally concave (optimism for all p) or globally convex (pessimism for all p) probability weighting *a priori*, and also implies that the fixed point where $w(p) = p$ occurs at $p = 0.368$ for any value of φ. The two-parameter function can admit concave and convex cases, and also inverse-S or S-shaped probability weighting with other fixed points. But allowing for the unrestricted joint distribution of random coefficients and selection/attrition errors leads to several extra parameters, making the use of the two-parameter function less practical for our purposes.[30]

[30] Allowing for the full set of correlations amongst two CRRA coefficients, two probability weighting coefficients, the selection error and the attrition error mean that the RDU specification with the one-parameter Prelec [1998] function already involves at least 13 more parameters to estimate than the EUT specification. The variance-covariance matrix of random parameters r_{n1}, r_{n2}, φ_{n1}, φ_{n2}, a_{n1} and a_{n2} is a 6-by-6 matrix with 15 distinct covariance parameters and 4 identified variance parameters. In comparison, the EUT specification involves 6 covariance parameters and 2 identified variance parameters. One should also estimate the population mean parameters for φ_{n1} and φ_{n2}, and those of r_{n1} and r_{n2}. Of course, the number of extra parameters increases even further when the mean parameters for the probability weighting function are conditioned on observed characteristics. We have also estimated the RDU model with the two-parameter Prelec specification and the results are available upon request. However, under this specification, one cannot easily define temporal stability of the probability weighting function. For example, one cannot identify the average or median person. While it is straightforward to identify the

One implication of the RDU model is that risk preferences are characterized by more than the concavity of the utility function. The risk premium is a complex function of all of the parameters that define the utility function as well as the probability weighting function. Indeed, a concave utility function might be mitigated by probability "optimism" such that the net effect is risk neutrality or even risk loving. We simply have to examine all parameters to characterize risk preferences in the case of RDU: r and φ.[31]

4. Results

We are interested in testing several hypotheses. First, is the distribution of risk attitudes in the general adult Danish population temporally stable over the one-year period we consider in the experiment? Second, are risk attitudes temporally stable at the individual level? Third, does the possibility of non-random sample selection and attrition change our inferences about the temporal stability of risk attitudes?

We use MSL to estimate the full statistical model that captures unobserved preference heterogeneity, endogenous selection into the first experiment, and endogenous panel attrition between the two experiments. Train [2009] provides details on MSL estimation of heterogeneous preference models without selection. Cappellari and Jenkins [2004] show how one can control for endogenous selection and attrition using MSL in the context of models without unobserved preference heterogeneity. By modeling the joint likelihood of observing the entire series of responses by each subject, and adjusting standard

---

mean and median of each parameter separately, a person with a mean or median value of η does not necessarily have a mean or median value of φ.

[31] The EUT model retains some descriptive value, however. The EUT and RDU models assume the same overall risk premium, even if they explain it differently. It is sometimes useful to focus on the parameter r in the EUT model as a summary statistic on the overall risk premium, even if the RDU model may provide the correct structural decomposition into aversion to outcome variability (the r parameter) and probability weighting (the φ parameter).

errors for clustering at the subject level, our statistical specification allows for "clustered" responses by the same subject. Panel-robust Wald statistics are used to test various hypotheses with respect to the estimated coefficients. The statistical model also allows for heteroscedasticity in the behavioral error term, by conditioning the noise parameter on binary variables for each treatment in the experimental design; one variable captures the order of risk aversion and discounting tasks, and the other variable captures our use of high and low stakes in the risk aversion tasks. We also condition the population mean coefficients of latent risk preference parameters on these two treatment variables.

We transform several estimates into alternative forms that are easier to interpret, and report correlation coefficients instead of covariance parameters. For the log-normal random coefficient φ in the RDU model, all results are for φ itself instead of ln(φ).[32] Finally, we divide selection and attrition equation coefficients by the normalized standard deviation of each equation so that they can be interpreted in the same manner as familiar probit coefficients.

A. Temporal Stability of Risk Attitudes

We find evidence of temporal stability for inferred risk attitudes under EUT when the model fully corrects for endogenous sample selection and attrition bias. Table C1 of Appendix C contains detailed estimates. Single hypothesis tests show that the mean CRRA parameter $\bar{r}_w$ for each treatment group is the same over time. For example, the estimated mean coefficient of relative risk aversion for the baseline case of our econometric model (when RAfirst = RAhigh = 0) is equal to 0.413 in wave 1, and equal to 0.594 in

---

[32] Specifically, we report the mean and median of φ for the base group (constant), along with the marginal effect of each observed characteristic on the mean and median of φ for the base group. The standard deviation of φ is evaluated at the sample average characteristics. The within-individual correlation of φ is computed by applying the usual formula for the correlation coefficient of bivariate log-normal random variables. Other correlations involving φ present cases where we compute the correlation between a log-normal random variable and a normal random variable. Garvey, Book and Covert [2015, p. 443, Theorem B.1] provide a closed-form formula that can be applied to these cases.

wave 2; the estimated difference in the two mean population coefficients is equal to 0.180, which is not significantly different from 0 with a *p*-value of 0.236.[33] The estimated population mean coefficient is also larger in wave 2 relative to wave 1 when we control for the high stakes treatment; the estimated difference between the two coefficients is 0.151, which is insignificant with a *p*-value of 0.294. We also find that the estimated population standard deviation of relative risk aversion is temporally stable; the estimated standard deviation of the r parameter, σ_r, drops from 0.856 in wave 1 to 0.787 in wave 2, and the estimated difference between the two coefficients is not significantly different (*p*-value of 0.637). A joint test of estimated mean population coefficients and standard deviation coefficients across the two waves allows us to evaluate whether the entire population distribution is temporally stable. The $\chi^2(4)$ test statistic has a *p*-value of 0.480, so we cannot reject the hypothesis of temporal stability.[34] Although the estimated population mean is higher in wave 2 compared to wave 1 for low and high stakes treatments, we find statistical evidence of temporal stability for the entire population distribution of relative risk aversion.

---

[33] Our risk aversion experiment was part of a larger experiment that involved a discounting choice tasks and a correlation aversion task. The order of risk aversion and discounting tasks was randomized on a between-subject basis; half of the subjects faced risk aversion tasks first (RAfirst = 1) and the remaining half faced discounting tasks first (RAfirst = 0). The correlation aversion task always followed the risk and discounting tasks. In each wave, each subject completed 20 risk aversion tasks that we classify as low stake (RAhigh = 0) and 20 decision tasks that we classify as high stake (RAhigh = 1). Our model allows for systematic variations in risk preferences across the order and stake treatments. To avoid potential clutter, our figures focus on comparisons across the stake treatments, since the order treatment effect is not statistically significant at the 5% level in any of our estimation results.

[34] Since the mean of the r parameter has been conditioned on two treatment variables, in each wave there are 3 estimates associated with the mean (constant, RAfirst, RAhigh). Temporal stability of the population distribution therefore entails 4 between-wave equality restrictions, comprising 3 restrictions on the mean and 1 restriction on the standard deviation.

The upper panel in Figure 1 shows the estimated population distributions of relative risk aversion across the two waves and two monetary treatments, with controls for non-random selection and attrition bias. The population distributions of relative risk aversion for both monetary treatments shift to the right in wave 2 compared to wave 1, but the apparent increase in risk aversion is *not* statistically significant, as noted above.[35] The marginal effect of the high stakes treatment on the estimated population mean is positive and the population distribution shifts to the right in both waves. The estimated coefficient of the high stakes treatment is equal to 0.088 with a *p*-value of 0.017 in wave 1, and equal to 0.059 with a *p*-value of 0.260 in wave 2. We thus observe a significant effect of the high stakes treatment on relative risk aversion in wave 1 and an insignificant effect in wave 2.

We next consider temporal stability at the individual level. The estimated correlation coefficient between relative risk aversion in wave 1 and 2, ϱ_{r1r2}, is equal to 0.360, which is significantly different from 0 (p-value < 0.001). The significant positive correlation suggests that risk preferences are temporally stable at the individual level, in the sense that someone with an above-average r parameter in wave 1 also tends to have an above-average r parameter in wave 2, and thus we reject the hypothesis that the two population distributions are independent.

Turning to the results for RDU, reported in detail in Table C2 of Appendix C, we draw mixed conclusions that depend on which aspect of temporal stability that one is interested in. Under RDU risk preferences are characterized by the r parameter as well as the weighting parameter, φ, which is log-normally distributed. The entire population distribution of risk preferences may be said to be stable when the joint distribution of r and φ is stable. More formally, this joint hypothesis requires stability in the estimated population means of the r and φ parameters, the estimated population standard deviations of r

[35] Figure 1 is generated from the *point estimates* of the population mean and population standard deviation of the relative risk aversion parameter. It does not reflect the *standard errors* around those point estimates, nor the covariance between them. Our statistical tests do take these into account.

and φ, and the estimated correlation between r and φ. We cannot reject this type of temporal stability; the associated $\chi^2(9)$ test statistic has a *p*-value of 0.303.[36]

Figure 2 displays the estimated population distributions of relative risk aversion for each wave and monetary treatment. The estimated distributions in the upper panel control for selection and attrition bias, and we observe that the estimated population means of the r parameter are almost identical across the two waves. The estimated between-wave difference in the population mean is 0.031 for the low stake treatment and 0.022 for the high stake treatment, and neither estimate is statistically significant. We also observe that the population distributions in wave 2 have a smaller standard deviation than the distributions in wave 1; the estimated standard deviation is 0.955 in wave 1 and 0.763 in wave 2, and we reject the null hypothesis that the estimated difference in the two coefficients is equal to 0 at the 5% significance level (*p*-value of 0.042). Hence, we find *temporal stability* with respect to population mean and *temporal instability* with respect to the standard deviation of the r parameter. The estimated correlation coefficient between the population distributions of the r parameter over time, ϱ_{r1r2}, is equal to 0.689, which is somewhat higher than the estimated coefficient under EUT, and we reject the hypothesis that the two population distributions are independent.

The estimated population distributions of the probability weighting parameter φ are displayed in Figure 3. The distributions in the upper panel control for selection and attrition bias, and we observe insignificant differences in the estimated population distributions of the φ parameter between the two waves. We cannot reject the hypothesis that the population distribution of the φ parameter is temporally stable; the $\chi^2(4)$ test statistic has a *p*-value of 0.306. The estimated difference in the population mean between the two waves is statistically insignificant across each monetary treatment, and we also find that

[36] The stable marginal distribution of the r parameter entails 4 restrictions. Similarly, the stable marginal distribution of the φ parameter entails another set of 4 restrictions. In total, temporal stability in the joint distribution of r and φ parameters entails 9 between-wave equality restrictions: 8 restrictions on the marginal distributions and 1 restriction on the correlation coefficient between the two parameters.

the standard deviation of the population distribution is temporally stable. The estimated standard deviation is higher in wave 2 compared to wave 1, but the estimated difference in the standard deviation is statistically insignificant (*p*-value = 0.326). Finally, we find that the estimated between-wave correlation of the φ parameter is 0.662 with a standard error of 0.159, which suggests that there is a strong degree of temporal stability at the individual level.

In summary, we contribute to the literature by modeling risk preferences in a non-linear, structural manner, allowing for unobserved heterogeneity across the population and endogenous selection and attrition. The use of panel correlations in structural parameters to test individual-level stability is also a unique feature of our analysis. The ability to analyze temporal stability at both the population and individual level in a single econometric model demonstrates the coherency and flexibility of our econometric modeling approach. Appendix D reviews related previous literature.

B. Effects of Sample Selection and Attrition on Risk Attitudes under EUT

We observe significant evidence of exogenous and endogenous selection and attrition effects on the estimated coefficients reported in Table C1. We find a positive and significant effect of the higher recruitment fee on the propensity to self-select into the first wave of our experiment. In effect, the law of demand applies to participation in the experiments, and response rates increase significantly when the recruitment fee is raised from 300 kroner to 500 kroner for participation in wave 1. We also find a statistically significant and U-shaped association between the self-selection index and the home-to-hotel distance, suggesting that there is a negative and diminishing marginal effect of the distance up to a turning point at 34.22 miles. In other words, as one may expect, people who live farther away from the session venues are less likely to participate, and people who live closer are more sensitive to a small increase in the distance. Of course the sign of the marginal effect changes after the turning point, but this is more or less an artefact of the quadratic specification that is of limited economic significance, since only six out of the 1996 invitees lived outside a 34.22-mile radius from a venue.[37] Looking at observable characteristics,

[37] All but one of the 1996 invitees lived within a 36.2-mile radius from a venue. The exceptional

middle aged and older subjects are more likely to select into the first wave compared to omitted age group. It is generally difficult to explain panel retention rates in terms of observed characteristics, although the results do suggest that young and high-income subjects are less likely to select into the second wave than otherwise.

Turning to endogenous effects of sample selection and attrition, we find enough statistical evidence to reject the hypothesis of no selection and attrition bias, respectively. The hypothesis of no endogenous sample selection bias is evaluated using the joint test of H_0: $\varrho_{s1s2} = \varrho_{s1r1} = \varrho_{s1r2} = 0$. This hypothesis is rejected, with a *p*-value less than 0.001. The hypothesis of no endogenous attrition bias can be tested by H_0: $\varrho_{s2r1} = \varrho_{s2r2} = 0$, which again is rejected, with a *p*-value less than 0.001. The estimated correlation coefficient between the error terms in the selection and attrition equations, ϱ_{s1s2}, is equal to -0.340 with a standard error of 0.125, which means that one cannot take the naïve approach of correcting for each source of sampling bias separately.

We can see the overall effects of controlling for selection and attrition bias on the estimated population distributions of relative risk aversion in Figure 1. The lower panel shows the estimated distributions with no correction for sample selection and attrition bias. Despite the significant statistical evidence of sample selection and attrition bias, we draw qualitatively similar conclusions about temporal stability. We observe that the population mean increases over time and the population distribution becomes tighter around the mean.[38] Although the estimated population mean is higher in wave 2 compared to wave 1 for both monetary treatments, there is statistically significant evidence of temporal stability with respect to relative risk aversion at the population level. We also find temporal stability at the individual level. The estimated correlation coefficient between relative risk aversion in wave 1 and 2 is equal to 0.537, which is significantly different from 0 (*p*-value < 0.001).

---

case was one subject that lived in Copenhagen but participated in the experiment in Århus.

[38] Table C3 in Appendix C reports the estimated parameters for the EUT model with no correction for selection and attrition bias.

Correcting for endogenous attrition is often easier than correcting for endogenous selection, since in the case of attrition one potentially knows a lot about the subjects that did not attend later waves from their participation in the very first wave. It would then be possible to correct for attrition bias under the assumption of no selection bias, as in Andersen, Harrison, Lau and Rutström [2008b]. When the maintained assumption fails, as in the present analysis, this may lead to a sharply different conclusion from the full approach that corrects for both types of biases. For example, only correcting for attrition bias would have led us to *reject* temporal stability in the population mean and standard deviation of relative risk aversion, with a *p*-value of 0.007.[39]

We do not claim that correcting for attrition bias under the assumption of no selection bias is less desirable than making no correction at all. This is an empirical issue that must be evaluated on a case-by-case basis.[40] Characterizing situations in which endogenous selection has substantive effects is an inherently difficult task, since it is correlation in *unobservables* that drives selection bias. The constructive implication of our analysis is that one can identify the effects of selection directly by adopting an experimental design that exogenously varies show-up fees, and avoid speculating on the presence and magnitude of selection bias.

C. Effects of Sample Selection and Attrition on Risk Attitudes under RDU

We continue to observe significant selection and attrition bias under RDU. The hypothesis test of no sample selection bias now involves the correlation coefficients between the error term in the selection

[39] Table C7 in Appendix C reports the estimated parameters for this EUT model with corrections for attrition bias and no corrections for selection bias.

[40] Whether correcting for only one type of bias worsens the overall bias or not depends on the interplay of all correlation coefficients pertaining to selection and attrition errors (in our case, ϱ_{s1s2}, ϱ_{s1r1}, ϱ_{s1r2}, ϱ_{s2r1} and ϱ_{s2r2}). There is no analytic formula, or even reliable intuition, that can provide a guide. This issue may be best addressed by a Monte Carlo study of misspecification biases under systematically varied patterns of correlations.

equation and the five other random components (the error term in the attrition equation, two r parameters, and two φ parameters). This hypothesis is rejected at all conventional levels, since the *p*-value is less than 0.001. The hypothesis test of no attrition bias involves the correlation coefficients between the error term in the attrition equation and four structural parameters (two r parameters, and two φ parameters) and we again reject the null hypothesis of no attrition bias (*p*-value < 0.001). The estimated correlation coefficient between the error terms in the selection and attrition equations, ϱ_{s1s2}, is equal to -0.416 with a standard error of 0.162, so we can again reject the naïve approach of correcting for each source of sampling bias separately.

Figure 3 displays the overall effects of controlling for selection and attrition bias on the estimated population distributions of the probability weighting parameter. The lower panel shows the estimated distributions with no correction for sample selection and attrition bias, and here we find statistical evidence of temporal stability.[41] More specifically, without corrections for non-random selection and attrition bias, we cannot reject the null hypothesis that the population distribution of the φ parameter is temporally stable (the $\chi^2(4)$ test statistic has a *p*-value of 0.304). Viewed another way, the uncorrected estimates of the probability weighting parameter seem relatively stable around biased base levels. We also observe that the shape of the population distribution for the weighting parameter changes when we correct for selection and attrition bias. Figure 3 shows that the population distribution of the φ parameter is more skewed to the right in the upper panel with corrections compared to the lower panel without corrections. A larger fraction of subjects can be classified by an inverse-S shaped probability weighting function when we correct for selection and attrition bias compared to the non-corrected estimates.

We can look closer at the effect of adding controls for sample selection and attrition on risk attitudes under RDU. The effects on the mean of the r parameter are modest: estimates of concavity slightly decline in both wave 1 and wave 2 when we control for selection and attrition bias, so the risk premium derived from utility concavity, *ceteris paribus*, is lower. The effects on the mean of the φ parameter

[41] The estimated parameters are reported in Table C4 in Appendix C.

are shown in Figure 4. The top (bottom) panel refers to the first (second) wave, and the left (right) panel refers to the low (high) stakes treatment. There are two outcomes in each lottery, and the probability weighting functions displayed in Figure 4 are identical to the implied decision weights on the highest outcome. Based on Figure 4 we can infer the effect of probability weighting on risk attitudes evaluated at the mean of φ. The S-shape of the probability weighting function leads to a negative (positive) risk premium for lotteries with a relatively high (low) probability of the highest outcome, *ceteris paribus*. We see similar S-shaped probability weighting across the two waves. While corrections for selection and attrition bias do not change our qualitative inferences regarding the shapes of the probability weighting functions, they lead to smaller mean estimates in both waves making the extent of probability distortion less pronounced. This finding on S-shaped probability weighting at mean values does not contradict the upper panel of Figure 3 that classifies a large fraction of the population as inverse-S instead: φ follows a right-skewed distribution, and the mean is sensitive to a long right tail.

We can again assess the potential error in assuming away selection bias and just correcting for attrition bias. As with EUT, this "second best" approach again leads to incorrect inferences.[42] Under RDU this approach would lead one to *reject* the hypothesis that the population mean and standard deviation of r and φ was temporally stable, with a two-sided *p*-value of 0.07.[43] This is again sharply different than the conclusion when correcting for both selection and attrition.

We can derive certainty equivalents for each lottery in Option A and Option B of the 40 decision tasks, and then evaluate the risk premia associated with different prize sets. Figure 5 displays the estimated risk premium in percent as a function of the probability of the highest outcome in lottery A with 2250 kroner and 1000 kroner and lottery B with 4500 kroner and 50 kroner. Lottery pairs like these were

---

[42] Table C8 in Appendix C reports the estimated parameters for the RDU model with corrections for attrition bias and no corrections for selection bias.

[43] Under EUT (RDU) the instability comes from the estimated mean (standard deviation) of the population parameter r.

presented in decision tasks that involved the largest stake within our experiment. The solid line is based on the estimated parameter values for r and η with corrections for selection and attrition bias, and the dashed line is based the model without correction for endogenous selection and attrition. The results show that *endogenous selection and attrition bias can have a substantive effect on the estimated risk premium*. For example, the upper right panel shows that the risk premium for lottery B with a 50-50 chance of 4500 kroner and 50 kroner is 1.7 percent of the expected value in the model with corrections for endogenous selection and attrition bias and is equal to 34.6 percent in the model with no control for selection and attrition bias.

5. Conclusions

Heckman and Smith [1995; p.99] noted that, "Surprisingly, little is known about the empirical importance of randomization bias." Aggregate data on participation rates from job training experiments by Hotz [1992] and clinical trials by Kramer and Shapiro [1984] suggest that the bias due to endogenous participation decisions might be significant, but we know of no study that directly evaluates the hypothesis.[44] We do not *a priori* know the direction of randomization bias in economics experiments, and whether the use of recruitment fees mitigates the effects of randomization bias on elicited risk attitudes. Given the importance of randomized control trials in policy experiments in economics, and concerns with inferences drawn from such designs (Harrison [2011a][2011b][2013]), there is surely some urgency to understand if randomization *per se* affects the latent characteristics of subjects.

[44] Many other hypotheses about the effects of sample selection and attrition in longitudinal studies have been evaluated, of course. In the case of clinical trials, for instance, Beunckens, Molenberghs and Kenward [2005] compare the effects of obvious *ad hoc* methods (such as assuming that the last observed case for some subject who does not participate in later sessions is the observation that the subject would have provided, or only using sub-samples that participate in all sessions), methods based on imputation and corrections for the imprecision of the imputation, and "direct-likelihood" methods such as those used here.

We find evidence of temporal stability for inferred risk attitudes under EUT when the model fully corrects for endogenous sample selection and attrition bias. A joint test of the estimated mean population coefficients for relative risk aversion and standard deviation coefficients for relative risk aversion, across the two waves, allows us to demonstrate that the entire population distribution of relative risk aversion is temporally stable. Furthermore, the estimated mean and estimated standard deviation of the population relative risk aversion are *each* temporally stable. Finally, the correlation of the population distribution of relative risk aversion is positive and statistically significant between waves, consistent with temporal stability at the individual level.

We obtain similar aggregate results for temporal stability under RDU, but with one difference. Under RDU the risk premium depends on utility curvature and probability weighting. When we consider the joint distribution of all parameters characterizing utility curvature and probability weighting, we cannot reject the hypothesis of temporal stability. This is what one would expect from the EUT results, since the two must agree in terms of the aggregate risk premium. But we find that there is temporal stability of the mean of the utility curvature parameter and *temporal instability of the standard deviation* of the utility curvature parameter. The parameter characterizing probability weighting demonstrates temporal stability. We again observe correlations between parameters over time, consistent with individual-level temporal stability.

These results are encouraging, in the sense that temporal stability allows policy-makers to have some sense of confidence when designing policies that affect risky outcomes over time, such as social insurance. But the results are particularly striking because *we also find statistically significant evidence of endogenous sample selection and attrition*. One might find temporal stability without making a correction for selection and attrition because the "raw data" is literally the same from wave to wave, or even the inferred risk preferences are literally the same from wave to wave. We conclude that one must make that correction, and that it results in changes in the averages and standard deviations of risk preference parameters: compare the top and bottom panels of Figure 1 under EUT and Figure 2 under RDU, and the two sets of probability weights in each panel in Figure 3 under RDU. These changes in risk preferences translate into economically significant changes in risk premia, as shown in Figure 5. Although we find evidence consistent with temporal stability with no corrections for selection and attrition, this is *temporal stability with respect to biased estimates of risk preferences*.

The effects of selection and attrition also accord with intuition. For example, we find a positive and significant effect of the higher recruitment fee on the propensity to self-select into the first wave of our experiment. And people who live farther away from the session venues are less likely to participate, and people who live closer are more sensitive to a small increase in the distance.

Our results therefore show that randomization bias can have significant effects on inferences about risk attitudes. Neglecting endogenous sample selection and attrition *could* lead one to draw erroneous conclusions about risk attitudes at a point in time (e.g. the average Dane's relative risk aversion now), as well as stability in risk attitudes over time (e.g. whether the average Dane's relative risk aversion has changed over time). In fact, we find that neglecting selection and attrition leads to the first type of erroneous conclusion but not, in general, to the second type of erroneous conclusion. These results hold whether one uses an EUT or RDU characterization of risk attitudes, although the way in which sample selection and attrition affects the analysis is different across the two decision theories as well as alternative measures of temporal stability that one may consider.

These effects of randomization bias on risk attitudes are clear in our design because of the exogenous variation in recruitment fees. We do not claim that our findings generalize beyond the adult Danish population, the specific recruitment fees we employed, or the battery of lotteries we employed. On the other hand, our sample is wide and representative of the adult Danish population, and our recruitment fees and lottery parameters fall well within common practice in field experiments. The constructive implication for future experimental design is to exogenously vary show-up fees and evaluate the effects on a case-by-case basis. Access to administrative data such as the Danish Civil Registry is not a prerequisite for operationalizing the proposed design. Recruiting experimental subjects from an existing household survey sample (e.g., Tanaka, Camerer and Nguyen [2010]) is an example of an alternative study design that allows one to obtain background information on non-participants. Of course, in the latter case, correcting for the effects of selection would lead to inferences that pertain to a survey population instead of a general population.

The need for corrections to mitigate randomization bias is "bad news" from our results, because it requires renewed attention to *ex ante* sample design and/or *ex post* statistical corrections. It also raises deep concerns with experimental designs that rely on randomization to infer causal effects, and that only check for consistency of observables over time. However, the "good news" is that even after making such corrections there are still many quantitative and qualitative aspects of risk attitudes that remain temporally stable, at least for this population and the time frame evaluated in our experiments.

Why is it that we observe such stability of risk preferences in Denmark, during a period in which all major industrialized countries experienced various macroeconomic disruptions? One hypothesis might be that the extensive social network of consumer protections in Denmark mitigated the effect of changes in these "background risks" on the "foreground" risk aversion our experiments measured. There is also evidence that Danes view the foreground risks of experiments as distinct from their extra-experimental wealth (Andersen, Cox, Harrison, Lau, Rutström and Sadiraj [2018]). The methodology we develop can be applied to different populations, to evaluate the extent to which they exhibit the same temporal stability of risk preferences.

Table 1: Sample Sizes and Descriptive Statistics

A. Sample Sizes

Recruitment	Variable	Wave 1	Wave 2	All
High Fixed Fee	Invited	865	184	1049
	Accepted	208	89	297
	Percent Accept	24.1%	48.4%	28.3%
Low Fixed Fee	Invited	1131	170	1301
	Accepted	205	93	298
	Percent Accept	18.1%	54.7%	22.9%

B. Descriptive Statistics for Participants

Variable	Definition	Mean Wave 1	Mean Wave 2
female	Female	0.48	0.45
young	Aged less than 30	0.16	0.13
middle	Aged between 40 and 50	0.23	0.21
old	Aged over 50	0.49	0.53
IncLow	Lower level income	0.22	0.23
IncHigh	Higher level income	0.47	0.45
Number of subjects		413	182

Notes: Most variables have self-evident definitions. The omitted age group is 30-39. Lower income is defined in variable "IncLow" by a household income in 2008 below 300,000 kroner. Higher incomes are defined in variable "IncHigh" by a household income of 500,000 kroner or more.

Appendix A: Instructions (WORKING PAPER)

We document the instructions for the risk aversion task that were given in hard copy to the subjects and a typical screen shot of the decision task. The original Danish version of the manuscript is available on request. The instructions were in 14-point font, printed on A4 paper, and handed out in laminated form.

Task L

In this task you will make a number of choices between two options labeled "A" and "B". An example of your task is shown on the right. You will make all decisions on a computer.

All decisions have the same format. In the example on the right Option A pays 60 kroner if the outcome of a roll of a ten-sided die is 1, and it pays 40 kroner if the outcome is 2-10. Option B pays 90 kroner if the outcome of the roll of the die is 1 and 10 kroner if the outcome is 2-10. All payments in this task are made today at the end of the experiment.

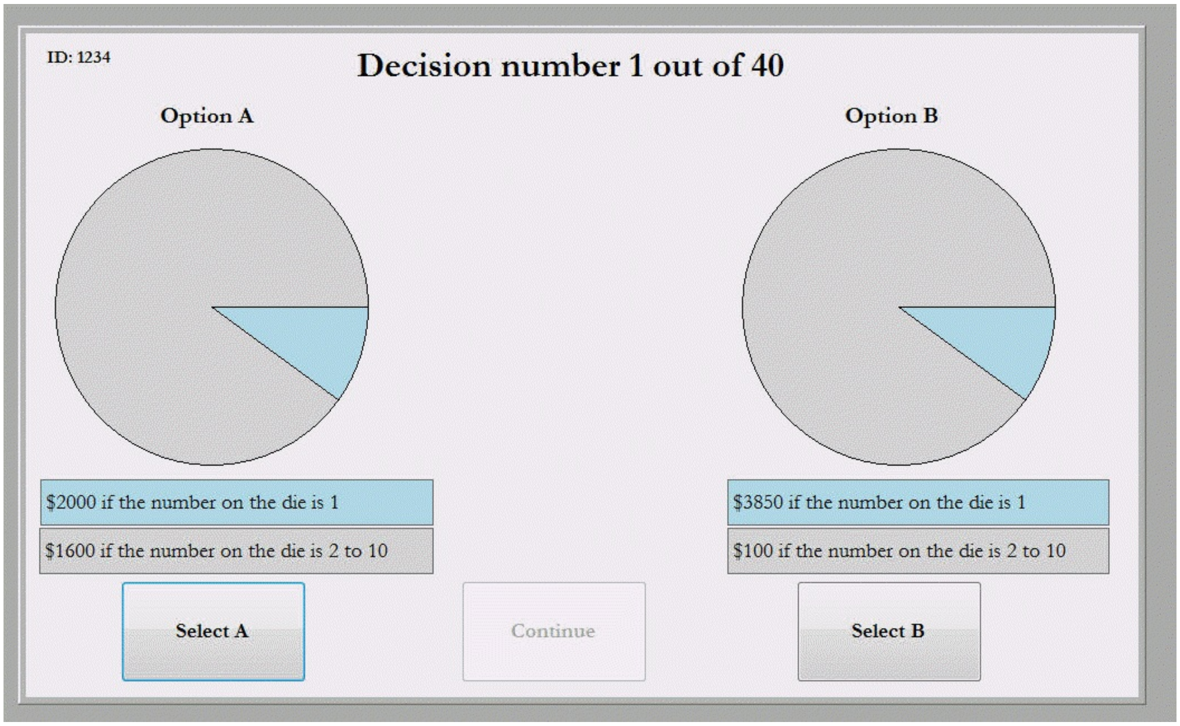
We will present you with 40 such decisions. The only difference between them is that the probabilities and amounts in Option A and B will differ.

You have a 1-in-10 chance of being paid for one of these decisions. The selection is made with a 10-sided die. If the roll of the die gives the number 1 you will be paid for one of the 40 decisions, but if the roll gives any other number you will not be paid. If you are paid for one of these 40 decisions, then we will further select one of these decisions by rolling a 4-sided and a 10-sided die. A third die roll with a 10-sided die determines the payment for your choice of Option A or B. When you make your choices you will not know which decision is selected for payment. You should therefore treat each decision as if it might actually count for payment.

If you are being paid for one of the decisions, we will pay you according to your choice in the selected decision. You will then receive the money at the end of the experiment.

Before making your choices you will have a chance to practice so that you better understand the consequences of your choices. Please proceed on the computer to the practice task. You will be paid in caramels for this practice task.

Typical screen shot



Appendix B: Exclusion Criteria and Experimental Design (WORKING PAPER)

We know of only two applications of the constructive approach to building exclusion restrictions into the experimental design.[45] Each example made an important methodological step by operationalizing a controlled basis for inferring selection bias or attrition bias. Nevertheless, neither example had access to information on non-participants that we have, nor considered the interaction between sample selection and panel attrition as we do.

The first example is the Survey Supply Experiment, undertaken as a module of the Index of Hospital Quality survey. Philipson [2001] analyzed data from this experiment, in which 23% of potential participants were randomized to the treatment group that would receive 50 US dollars for returning the survey questionnaire, whereas the control group faced no such incentive. The financial incentive resulted in a higher response rate of 59.3% for the treatment group of 121 randomly selected physicians, in comparison with a response rate of 50% for the control group of 298 physicians. The estimated mean income of the physicians in the sample became 50% larger after correcting for selection bias. The missing information on non-participants, however, meant that the effects of selection were identified by some strong *ad hoc* assumptions about the effects of the financial incentive and survey response rates on the uncorrected mean income.[46]

The second example is the follow-up for the Longitudinal Movement to Opportunity (MTO) field experiment, in which 30% of the sample was randomly assigned to more intensive follow-up: see Orr et al. [2003; Exhibit B, §B1.3] and DiNardo, McCrary and Sanbonmatsu [2006]. This randomized follow-up was in addition to the primary randomization to treatment: (i) a housing voucher with some strings attached and some counseling, (ii) a housing voucher with no strings attached and no counseling, and (iii) a control group. This additional randomization to more intensive follow-up had virtually no effect on results, however, since the effective response rates for the long-term MTO follow-up were around 90% and similar across primary treatments (Sanbonmatsu et al. [2011; p. 259]).[47]

---

[45] One may find more examples when focussing on conceptual plans instead of actual applications. For instance, in evaluating the serious effects of attrition on psychotherapy, Leon et al. [2006; p. 1004] noted in passing that a "... very simple, yet overlooked, strategy for dealing with the inevitable problem of dropout is to collect data that can help predict attrition." What they had in mind, following Demirtas and Schafer [2003], was to ask subjects how likely it was that they would show up again, but they also raised the possibility of offsetting transportation or logistical costs (p. 1004), which is related to our design with differential financial incentives for participation.

[46] Specifically, it was assumed that the uncorrected mean income was an increasing function of the financial incentive (Philipson [2001, p. 1101]) and was linear in survey response rates (Philipson [2001, p. 1109]).

[47] In many respects a similar methodological approach is employed by Behaghel, Crépon, Gurgand and Le Barbanchon [2009]. They evaluate two independent surveys of virtually the same population of job seekers in France: one survey involved a long telephone survey and had a 50% response rate, and the other survey involved a short telephone survey, augmented by administrative data, and had a higher 80% response rate. Using non-parametric methods from Horowitz and Manski [2000] and Lee [2009], they show that the two surveys lead to dramatically different estimates of the effects of career counseling programs on job search outcomes, arguing that the first survey suffers from severe selection bias.

A key feature of the inferential problem considered in our experiment is that the "outcome variable" of interest is a *latent* characteristic: risk aversion. The context is fundamentally different from the cases that Philipson [1997][2001] considered, initially in a thought experiment (Philipson [1997, §3]) and later in an empirical analysis (Philipson [2001]), where one could use randomized recruitment fees to remove selection bias from the estimated mean of an *observable* characteristic. This also means that we cannot replace data from subjects exhibiting non-response with administrative data, as many studies have done to assess the seriousness of sample selection and attrition (e.g., Grasdal [2001], Behaghel et al. [2009] and Ludwig et al. [2013]).

There is some evidence from clinical drug trials that persuading patients to participate in randomized studies is much harder than persuading them to participate in non-randomized studies (e..g., Kramer and Shapiro [1984; p.2742ff.]). The same problem applies to social experiments, as evidenced by the difficulties that can be encountered when recruiting decentralized bureaucracies to administer random treatments (e.g., Hotz [1992]). For example, Heckman and Robb [1985] note that the refusal rate in one randomized job training program was over 90%. With the renewed popularity of randomized control trials in social sciences, evaluation of the potential effects of "randomization bias" is urgent.[48] Our methods of controlling for endogenous sample selection and attrition have broader applications to randomized control trials that consider causal effects of treatments on latent variables of interest in economic policy, such as welfare effects (Harrison [2011a][2011b][2013]).

[48] This is also true, of course, for the effects of attrition in general. Hausman and Wise [1979; p. 455ff.] note that attrition "...may negate the randomization in the initial experimental design. If the probability of attrition is correlated with experimental response, then traditional statistical techniques will lead to biased and inconsistent estimates of the experimental effect."

Notes: Group means (medians) are predicted using the estimated mean (median) function for each parameter. ∆Base tests whether the between-wave difference in constant is significant. ∆RAhigh, ∆RAfirst, and ∆high_fee test whether the between-wave differences in constant + RAhigh, constant + RAfirst and constant + high_fee are significant, respectively.

Appendix D: Relationship to Previous Literature (WORKING PAPER)

Glöckner and Pachur [2012] and Zeisberger, Vrecko and Langer [2012] estimate one set of structural parameters for Cumulative Prospect Theory for each individual subject, and compare the *point estimates* over one-week and one-month time periods, respectively. Their statistical tests of temporal stability, however, do not fully account for random sampling variations in the estimates. Hey and Orme [1994] were the first to consider individual level estimation of latent risk attitudes, which requires a sufficiently large number of observations per subject; they had a sample of 80 subjects with 100 observations per subject. Later applications of individual level estimation of latent preferences also consider individual discount rates (Andersen, Harrison, Lau and Rutström [2014]), risk preferences (Harrison and Ng [2016]), and intertemporal correlation aversion (Andersen, Harrison, Lau and Rutström [2018]). To control for endogenous sample selection and/or attrition bias and study temporal stability at the population level one must pool observations over all subjects and estimate the population distributions of individual level coefficients, which we do.

Andersen, Harrison, Lau and Rutström [2008b] analyzed the stability of risk preferences in the same population, but with a different sample, between June 2003 and November 2004. They find evidence of stable risk preferences. Harrison, Lau and Rutström [2007] focussed on the analysis of the first experiment in June 2003, and found that the average Dane was risk averse. However, neither study randomized incentives for participation, and neither study undertook corrections for endogenous selection into the initial experiment. Nor did they consider unobserved preference heterogeneity and the possibility of probability weighting under RDU.

We use large monetary incentives compared to most other experiments on individual choice under risk. For example, the prizes in our two high stakes treatments are roughly twice as high as those paid by Holt and Laury [2002] in their 90x treatment, which paid 90 times the low payoff level in their experimental design. The prizes in our two small stakes treatments are scaled down by 50% compared to the prizes in the two high stakes treatments, which in nominal terms is a difference of 2,500 kroner if one compares the highest prize (4,500 kroner) in the fourth prize set with the highest prize (2,000 kroner) in the second and third prize set. Although the scaling of prizes between the high and low stakes treatments may seem low in relative terms, these are substantial differences in absolute terms to most Danes.

Harrison, Lau and Rutström [2007][2009] use data from a single panel of a previous Danish field experiment that was conducted in June 2003 and correct for sample selection in the analysis of risk attitudes. They only consider EUT specifications of risk preferences, and combine linear, interval regression models of chosen CRRA intervals with probit selection models. Invitations to participate in the field experiment were sent out to 664 randomly selected adult Danes across the country, and all subjects were informed that they would be paid 500 kroner to participate in the experiment and could earn an additional sum of money. The results show that the recruited sample of 253 subjects is significantly more risk averse than the general population, but the estimated marginal effects of individual characteristics are similar with and without correction for sample selection. Harrison, Lau and Rutström [2009] use data from two additional Danish lab experiments with similar decision tasks as those in the field experiment. The first lab experiment was conducted in October 2003 with a sample of 90 subjects recruited from the University of Copenhagen and Copenhagen Business School. Each subject was paid 250 kroner to participate in the experiment. The second lab experiment was conducted in November 2006 with a new sample of 35 students. Subjects were randomly divided across two recruitment treatments: compared to the control group in the first lab experiment, one treatment reduced the recruitment fee to 100 kroner, and the other treatment scaled all prizes in the experiment down by 50%. The analysis does not control for endogenous sample selection bias and is again based on a linear, interval regression model with chosen CRRA intervals modeled as a function of the recruitment treatments and other experimental treatments. The results show that treatments with higher recruitment fees lead to samples with more risk averse subjects than otherwise. Our present approach considers RDU as well as EUT, explicitly models the latent non-linear structural model rather than the "CRRA interval reduced form" choices, allows for unobserved preference heterogeneity, allows for endogenous sample selection, and allows for endogenous attrition.

The one-parameter Prelec function is similar to another one-parameter function popularized by Tversky and Kahneman [1992]: $w(p) = p^{\gamma} / (p^{\gamma} + (1-p)^{\gamma})^{1/\gamma}$, which is inverse-S ($\gamma < 1$) or S-shaped ($\gamma > 1$). When φ=1 and η is a free parameter instead, (12) collapses to the power function $w(p) = p^{\eta}$; this function can capture either probability optimism ($\eta < 1$) or pessimism ($\eta > 1$), but not both at the same time. There are several versions of the Prelec [1998] function, since several were specified in his Proposition 1 (p.503). We do not use his versions (A) or (B) that constrain φ to be in the unit interval, since that constraint rules out "S-shaped" probability weighting *a priori*, which we view as an unattractive restriction. The one-parameter function we use is a special case of version (C) in his Proposition 1.

To the best of our knowledge, our study is the first to parameterize within-individual correlation in risk attitudes over time as part of a structural model, and also the first study to control for the effects of selection and attrition on the associated inferences. The magnitudes of our estimates appear plausible considering what previous studies found using alternative approaches. Based on a review by Chuang and Schechter [2015, p.153, Table 1], we can identify four experimental studies with real incentives that reported within-individual correlation in risk attitudes over time. Levin, Hart, Weller and Harshman [2007] and Lönnqvist, Verkasalo, Walkowitz and Witchardt [2015] used the raw count of safe choices from pairwise comparisons to measure risk aversion, and found correlation ranging from 0.20 to 0.38. Andersen, Harrison, Lau and Rutström [2008b] assumed EUT with CRRA utility to derive each subject's r parameters from their responses to multiple price list tasks, and found correlation in the derived r parameters ranging from 0.34 to 0.58 (compared to our estimate of 0.36). Finally, Wölbert and Riedl [2013] applied a two-step approach of estimating a RDU model separately for each subject and wave, and using the resulting point estimates as data points in subsequent statistical analyses.[49] They assumed CRRA utility and one-parameter Prelec probability weighting functions, and computed correlation of 0.77 in the r parameters and 0.73 in the φ parameters (compared to our estimates of 0.69 and 0.66, respectively).

Appendix E: Incorporating Observed Heterogeneity (WORKING PAPER)

We have estimated the population distributions of structural parameters to account for interpersonal heterogeneity in risk preferences. An alternative way to capture preference heterogeneity is to generalize representative agent models by allowing structural parameters to vary with observed personal characteristics. This type of observed heterogeneity can be incorporated into our analysis by conditioning the population mean of each parameter on the decision maker's characteristics, in the same manner as we have conditioned the mean of each parameter on the treatment variables.

To illustrate the approach, we replace the two treatment variables with a female dummy and estimate models that focus on the overall male-female differences in risk preferences. As in our main analysis, we use the contextual utility model of Wilcox [2011] to account for behavioral errors. Despite the common assertion that women are more risk averse than men, the supporting evidence is not ubiquitous and previous studies in Denmark do not find significant male-female differences in risk attitudes (Harrison, Lau and Rutström [2007; p.361]). Figure E1 displays the estimated population distributions of the r and φ parameters under the RDU model with correction for selection and attrition biases. We observe that women are more risk averse than men with a significant male-female difference in the mean of the r parameter in wave 1, and an insignificant difference in relative risk aversion in wave 2. However, there is no significant male-female difference in either the mean or the median of the φ parameter.[50] We also draw different conclusions about temporal stability for men and women in terms of relative risk aversion: there is a significant between-wave change in the mean of the r parameter for women (*p*-value = 0.008) but an insignificant between-wave difference for men (*p*-value = 0.900). There is no significant between-wave difference in the mean and median of the φ parameter for both men and women, however, and the probability weighting function is temporally stable for both representative agents. The hypotheses of no selection bias and no attrition bias are rejected at the 1% level. Without correction for selection and attrition biases, our conclusion on temporal stability in the r parameter would have been reversed; we would have found that there is a significant between-wave change in the mean of the r parameter for men but not for women (*p*-values of 0.006 and 0.673).[51]

[50] The male-female difference in the mean of the r parameter is 0.527 (*p*-value < 0.001) in wave 1 and 0.280 (*p*-value = 0.063) in wave 2. The difference in the mean of the φ parameter is -0.329 (*p*-value = 0.144) in wave 1 and -0.260 (*p*-value = 0.581) in wave 2. Finally, the difference in the median of the φ parameter is -0.159 (*p*-value = 0.106) in wave 1 and -0.106 (*p*-value = 0.188) in wave 2.

[51] Table E2 in the present appendix reports detailed estimation results for the preceding discussion.
